Fig. 1. Example of four different mesh editing algorithms implemented with our library. With our framework, users can implement different flavor of mesh editing with built in robustness, and readily available parallelism. From left to right: harmonic triangulation, QSlim, the input, isotropic remeshing, and robust tetrahedral mesh generation.

We introduce a novel approach to describe mesh generation, mesh adaptation, and geometric modeling algorithms relying on changing mesh connectivity using a high-level abstraction. The main motivation is to enable easy customization and development of these algorithms via a declarative specification consisting of a set of per-element invariants, operation scheduling, and attribute transfer for each editing operation.

We demonstrate that widely used algorithms editing surfaces and volumes can be compactly expressed with our abstraction, and their implementation within our framework is simple, automatically parallelizable on shared-memory architectures, and with guaranteed satisfaction of the prescribed invariants. These algorithms are readable and easy to customize for specific use cases.

1 INTRODUCTION

Unstructured triangular and tetrahedral meshes are widely used in graphics, engineering, and scientific computing due to their flexibility to represent objects with complex boundaries. Such unstructured meshes find their usage in modeling and rendering 3D objects and scenes, discretizing partial differential equations for physical simulation, collision detection and response, path planning in robotics, and many other applications.

An unstructured mesh is usually stored in a custom data-structure supporting a set of local operations to add, remove, or change its elements and their properties. A major research effort has been invested in exploring different data-structures and evaluating their generality and efficiency (Section 2), which led to the development of mesh
libraries such as CGAL [The CGAL Project 2020], VCG/meshlab [Cignoni et al. 2021], OpenMesh [Botsch et al. 2002], libigl [Jacobson et al. 2016], PMP [Sieger and Botsch 2019], and OpenVolumeMesh [Kremer et al. 2013]. Commonly, mesh-editing algorithms (i.e., algorithms based on operations changing the connectivity of a mesh) are tightly coupled with a data-structure and its API, and porting an algorithm from one library to another is a major engineering effort. Code relying on local operations is also inherently error prone, as it usually involves keeping track of properties attached to mesh elements as the mesh itself changes due to the local operations. Parallelizing code using a mesh data structure is also challenging, due to race conditions when multiple threads attempt to change the same region of the mesh.

At a high-level, it is common practice to describe a mesh editing algorithm as a sequence of topological and geometrical editing operations. We argue that this approach is unnecessarily low-level, as it exposes the algorithm designer to technical problems that can be handled automatically by changing the abstraction level. It also makes it challenging to use or customize mesh editing algorithms in larger projects (such as their use in physical simulation for adaptive refinement), as low-level data structure details percolate in the entire code-base. A particularly difficult challenge in these algorithms is to ensure that a set of conditions (such as manifoldness, being free from self-intersections, minimal quality, maximal geometrical approximation) hold after each operation is applied. This is usually tackled by simulating each operation for the purpose of checking these conditions, an error-prone process that needs to be carefully designed for each pair of operation and condition. The additional presence of attributes attached to vertices, edges, or faces further complicates these problems.

We propose a different way to describe mesh-editing algorithms on simplicial manifold meshes, using a declarative specification instead of a more traditional procedural approach. Instead of focusing on what the algorithm does, we ask the user to specify what are the requirements that the desired mesh should have. We divide these requirements into two groups: invariants and desiderata. The former is a description of hard requirements on the mesh (for example, no inverted elements or no self-intersections) and the latter is a set desirable properties (such as good quality). A mesh editing algorithm is then described as: (1) a set of per-element invariants (for example, all elements should have correct orientation), (2) a measure for the desiderata (for example, element quality), (3) a set of application-specific attributes attached to mesh elements (e.g., vertex coordinates), and how they are affected by local operations, and (4) a schedule of operation types. We show that many existing algorithms for mesh generation, remeshing, and parametrization, can be concisely expressed in this form (Section 4), which we denote IDAS (Invariant-Desiderata-Attributes-Schedule).

The IDAS specification has been designed with four goals:

1. **Modularity:** The connectivity of the mesh is abstracted from the user, which can only navigate the mesh using a high-level abstraction based on a cell tuple [Brisson 1989]. This reduces the learning curve for new users, as they only need to learn a navigation API to implement algorithms in IDAS. It will also allow IDAS programs to benefit from continuous progress in data-structure design, as the data structure will be swappable without requiring downstream code changes in the high level IDAS code. This is in stark contrast with existing mesh libraries, which tend to be very invasive in the user code relying on them due to the close connection between navigation, mesh editing, and property management.

2. **Usability:** The user code handles, at all times, a valid mesh: the library simulates each operation transparently allowing the user to navigate on a valid mesh before and after every operation, dramatically simplifying the logic required to define invariants and desiderata. Properties on the mesh are also similarly abstracted, allowing to attach attributes on every simplex independently on the data structure used for implementing the specification.

3. **Efficiency:** The specification purposely requires only definitions of properties on individual elements. This feature allows runtimes for IDAS program to parallelize the computation (Section 4) without requiring special attention from a user. We demonstrate that automatic parallelization of mesh editing algorithms is possible on multi-core architectures.

4. **Robustness:** The IDAS specification moves the majority of the robustness issues typical of meshing algorithm on the runtime used to execute a IDAS program instead of the IDAS code itself. This simplifies the development of robust algorithms: for example, the user invariants are guaranteed to be enforced during processing, as the runtime will automatically check them on every modified element. As long as the user provides correct code for the invariant (for example to check for area positivity of an element using a predicate), then the runtime ensures that the invariants will be satisfied for all elements.

Given an algorithm in IDAS form, we design an algorithm and runtime library to realize it, with guarantees on satisfying the invariant and a best effort to maximize the desiderata. Our library exploits shared memory parallelism without any additional effort required from users in the algorithm specification.

To demonstrate the generality and effectiveness of our approach, we provide IDAS formulations for five popular mesh editing algorithms (Section 4, Figure 1): (1) shortest edge collapse [Hoppe 1996] (decimation for triangle meshes), (2) QSLim [Garland and Heckbert 1997], (3) isotropic triangle meshing [Botsch and Kobbelt 2004] (remeshing for triangle meshes), (4) harmonic triangulations [Alexa 2019] (quality improvement for 3D volumes), and (5) robust tetrahedral mesh generation [Hu et al. 2019b] (conversion of surface meshes to volumetric meshes). The IDAS formulation closely resemble the textual description of the algorithms in the corresponding papers: it is compact, readable, and easy to adapt for requirements of specific applications. As an example, we show that modifying (1) and (2) to guarantee a maximal geometric error is straightforward. Despite its generality, IDAS implementations executed using our library are comparable or faster than state of the art implementations in open-source software: the overhead due to the framework generality is more than compensated by the automatic parallelization (Section 4).
We believe our contribution is an important step to allow researchers and practitioners to effectively develop new mesh-editing algorithms, shielding the designer of mesh editing algorithms from many of the robustness and correctness challenges plaguing previous low-level approaches, by moving these components inside the runtime environment. It will also allow mesh editing algorithms to be used more easily in larger systems, as they can be tailored to requirements of a specific application with minimal programming effort.

We provide an open-source implementation ¹ of our library and of the five mesh editing algorithms as additional material.

2 RELATED WORK

2.1 Mesh Data Structures

Efficient data structures for representing solid geometry have been an intriguing research topic since the early days of computer graphics [Requicha 1980]. As a result, there is a large variety of mesh data structure designs, where they are each optimized for different usage scenarios. Index-array-based mesh data structure encodes each element as a list of vertex indices on its boundary. It is simple and memory efficient, but neighborhood query and local operations are not directly supported. Graph-based mesh data structures, including half-edge [Mäntylä 1987], winged-edge [Baumgart 1972], quad-edge [Guibas and Stolfi 1985], cell-tuple [Brisson 1989], etc., view meshes as graphs, where each element contains links to its adjacent elements. This design allows for efficient local query and update, making it ideal for algorithms like mesh simplification [Garland and Heckbert 1997]. Linear-algebra-based mesh data structures, such as [DiCarlo et al. 2014; Mahmoud et al. 2021; Zayer et al. 2017], encode adjacency information as sparse matrices. This design elegantly reduces neighborhood query and local operations to sparse matrix computations, which are highly optimized for modern parallel computing architecture. Closely related, is the concept of generalized combinatorial maps [Dufourd 1991; Lienhardt 1994], and the CGoGN library [Kraemer et al. 2014] provide an efficient implementation which includes parallel traversal of the mesh. By design, mesh data structures provide a low level interface to manipulate vertices, edges, faces, and tetrahedra. Different designs differ vastly in API and implementation details, making it hard to port algorithm from one data structure to another. In contrast, our framework decouples mesh data structure choice from algorithm specification, providing the flexibility of switching the underlying data structure in a seamless manner.

2.2 Domain specific languages in graphics

Our abstraction model of mesh processing algorithms draw inspiration from domain specific languages (DSL) in graphics. For dense regularly structured data such as images, Halide [Ragan-Kelley et al. 2013] popularized the idea of decoupling image processing operations from low level scheduling tasks. Similar abstraction that separates algorithm description from low level data structure and/or parallel architecture can also be found in other DSLs such as Simit [Kjolstad et al. 2016] for simulation over triangle meshes, Taco [Kjolstad et al. 2017] for dense and sparse tensor algebra, Taichi [Hu et al. 2019a] for simulation over sparse volumetric data, and Penrose [Ye et al. 2020] for generating diagrams from math notation.

2.3 Parallel Meshing

To meet the demand of generating large meshes, a number of popular mesh generation algorithms have been redesigned to leverage modern parallel computing hardware, both in a shared memory and distributed memory setting. Typically a divide-and-conquer strategy is adopted where a mesh is partitioned to run local processing operations on each subdomain in parallel. There are two key challenges involved: (1) how to handle operations involving elements shared by multiple partitions; (2) how to ensure load stay balanced across different processors as the mesh evolves.

One way to mitigate both challenges is to ensure mesh is partitioned into similar sized patches with high area to boundary ratio. A large number of partitioning strategies are available, including clustering-based approaches [Mahmoud et al. 2021], special-hierarchy-based approach [Lo 2012; Loseille et al. 2017], space-filling-curve-based approach [Borrell et al. 2018; Marot et al. 2019], and general purpose graph partitioning [Karypis and Kumar 1998]. Many variations of space-filling curves have also been used to construct mesh partitions [Aluru and Sevilgen 1997; Chrissoides 2006]. To handle potential conflicts that may arise at partition boundaries, various synchronization strategies have been proposed [Chrissoides 2006; Chrissoides and Nave 2003; Okusanya and Peraire 1996] to minimize the amount of communication.

After generating the submeshes, some methods allow each compute node to work on them independently without synchronization. Once all threads are done, the meshes are merged [Blelloch et al. 1999; Chen 2010; Cignoni et al. 1993; Funke and Sanders 2017]. However these methods require complicated merge steps since the tetrahedra in the intermediate boundaries may not align. There are some techniques that compromise the Delaunay condition in some cases, so that the merging operation can be simpler [Lachat et al. 2014]. To avoid the tricky merge operations, other parallel strategies maintain a single complete Delaunay tetrahedralization and use synchronization techniques to avoid race conditions when working on a partition boundary [Chrissoides and Nave 2003; Okusanya and Peraire 1997]. The parallel constrained Delaunay meshing algorithm [Chew et al. 1997] cleverly defines the boundary and edge constrains to reduce the variable and unpredictable communication patterns. Some other techniques use locks for handling conflicts and data races [Batista et al. 2010; Blandford et al. 2006; Foteinos and Chrissoides 2011].

Another set of methods use recursive divide-and-conquer techniques for parallel implementation on shared memory machines [Marot and Remacle 2020]. All threads independently work on the internal parts of the mesh and skip the operations at the boundary. After this phase, processing of only the boundary elements becomes the new problem. This technique is then recursively used until all the mesh elements are processed. A similar set of techniques use clever space-filling curves for re-partitioning the mesh boundaries after each recursive phase [Aluru and Sevilgen 1997; Chrissoides 2006].

¹https://github.com/wildmeshing/wildmeshing-toolkit
Since the submesh boundaries are the main areas of concern, some methods entirely avoid any operations on these boundaries while ensuring the correctness of the result [Gallier and George 1996; Linardakis and Chrissochoides 2006]. These methods precompute the domain separators such that their facets are Delaunay admissible. This completely eliminates synchronization overheads, but only applies for Delaunay meshing.

Another conflict handling strategy is to simply reject the offending operations and try executing them later with a new domain partitioning [Marot et al. 2019]. This reject-and-repartition strategy may not guarantee algorithm termination, thus special care is needed to handle this case.

As the domain mesh evolves, keeping load balanced across processors becomes critical. Typically, this is done by periodically repartitioning the updated mesh. Zhou et al. [2012] proposes a predictive load balancing method to keep partitions balanced. Marot et al. [2019] uses simple rescaling of the space-filling curve to repartition the domain.

In this work, we are targeting only shared-memory parallelism, thus making the problem of reducing communications between processors less relevant. We use a graph-based space partitioning technique [Karypis and Kumar 1998] due to its simplicity and availability as open-source code (METIS), but we use it only to reduce the risk of conflicts. To avoid conflicts, we use a shared memory locking mechanism. This approach is only possible for shared-memory parallelism but has the major advantage of not requiring rebalancing and to respect, to a certain degree, the execution order prescribed by the user-code. This approach is possible thanks to the availability of efficient parallel atomic instructions, and parallel libraries based on them (oneTBB).

### 2.4 Scope of Mesh Editing

**Mesh Generation.** Tetrahedral meshing algorithms heavily rely on mesh editing operations. The most common approaches are Delaunay methods [Alliez et al. 2005a; Bishop 2016; Boissonnat et al. 2002; Boissonnat and Oudot 2005; Busaryev et al. 2009; Chen and Xu 2004; Cheng et al. 2008, 2012; Chew 1989; Cohen-Steiner et al. 2002; Dey and Levine 2008; Du and Wang 2003; Jamin et al. 2015; Murphy et al. 2001; Remacle 2017; Ruppert 1995; Shewchuk 1996, 1998, 2002; Si 2015; Si and Gartner 2005; Si and Shewchuk 2014; Tournois et al. 2009], which strive to generate meshes satisfying the Delaunay condition, grid methods [Bern et al. 1994; Bridson and Doran 2014; Bronson et al. 2013; Doran et al. 2013; Labelle and Shewchuk 2007; Molino et al. 2003; Yerry and Shephard 1983], which start from a regular lattice or with a hierarchical space partitioning and optionally intersect the background mesh with the input surface, and front-advancing methods [Alaizuet and Marcuun 2014; Cuilliere et al. 2013; Haines 2014; Sadek 1980], which insert one element at a time, growing the volumetric mesh (i.e. marching in space), until the entire volume is filled.

These algorithms rely on local operations on mesh data-structures, and benefit from our framework to simplify the implementation and gain automatic parallelization. We discuss an implementation of one of the more recent algorithms [Hu et al. 2019b, 2018] in Section 4. Note that some of these algorithms use local operation that are not implemented yet (such as 5-6 swap), but they could be added to our framework.

**Constrained Meshing.** Downstream applications often require meshes to satisfy either quality (avoidance of zero volume elements) or geometric (distance to the input surface) constraints. For example, Mandad et al. [2015] creates a surface approximation within a tolerance volume, the TetWild algorithms [Hu et al. 2019b, 2018] use an envelope [Wang et al. 2021] to restricts the geometry of the boundary of the tetrahedral mesh, [Brochu et al. 2012] adds constraints to local remeshing to avoid interpenetrations in simulations, and [Gumhold et al. 2003] extends mesh simplification [Garland and Heckbert 1999; Popović and Hoppe 1997] to ensure a non self-intersecting result.

These criteria are explicitly modeled as invariants in our framework, and they can be easily swapped in and out existing implementations, as we demonstrate in Section 4.

**Mesh Improvement.** Mesh improvements modifies an existing mesh by changing its connectivity and position of the vertices to improve the quality of its elements [A. Freitag and Ollivier-Gooch 1998; Alexa 2019; Alliez et al. 2005b; Canann et al. 1996, 1993; Chen and Xu 2004; Feng et al. 2018; Hu et al. 2018; Klingner and Shewchuk 2007; Lipman 2012]. We show in Section 4 a reimplementation of [Alexa 2019] in IDAS form.

**Dynamic Remeshing and Adaptive Mesh Refinement (AMR).** Simulations involving large deformations are common in computer graphics, and if the surface or volume deformed is represented by a mesh, it is inevitable that after a large deformation the quality of the elements will deteriorate, and the mesh will have to be updated. Additionally, it is often required to concentrate more elements in regions of interest whose location is changing during the simulation, for example to capture a fold in a cloth simulation, or a fracture in a brittle material. These two challenges are tackled in elastoplastic and viscoplastic simulations [Bargteil et al. 2007; Hutchinson et al. 1996; Wicke et al. 2010; Wojtan and Turk 2008], in fluid simulations [Ando et al. 2013; Chentanez et al. 2007; Clausen et al. 2013; Klingner et al. 2006; Misztal and Bærentzen 2012], in cloth simulation [Bender and Deul 2013; Li and Volkov 2005; Narain et al. 2013, 2012; Pfaff et al. 2014; Simnett et al. 2009; Villard and Borouchaki 2002], and fracture simulation [Busaryev et al. 2013]. All these algorithms could benefit from our contribution, to simplify their implementation and obtaining speedup due to the automatic parallelization offered by our approach.

A different approach is discussed in [Grinspun et al. 2002], where the refinement is performed on the basis to avoid the difficulties with explicit remeshing. However, this approach cannot coarsen a dense input, and also cannot increase the quality of elements, making it usable only for specific scenarios [Grinspun et al. 2002]. Our approach aims at lowering the barrier for integrating explicit remeshing algorithms in simulation applications, thus allowing to directly use standard simulation methods on adaptive meshes without having to pay the high implementation cost for the mesh generation.

When remeshing is paired with algorithms simulating contacts that do not tolerate interpenetrations (for example [Li et al. 2020]),
it is necessary to ensure that adaptive remeshing does not break this invariant. This can be achieved adding non-penetration constraints to each local mesh editing operations, as proposed in [Brochu et al. 2012]. Our framework is ideal for developing such methods, as additional constraints can be added to existing mesh editing algorithms with minimal modifications, as we demonstrate in Section 4.

**Parametrization.** Conformal mesh parametrization algorithms adapt the mesh during optimization, as a a fixed triangulation restricts the space of metrics realizable [Campen et al. 2019; Campen and Zorin 2017a,b; Gu et al. 2018a,b; Luo 2004; Springborn 2020; Sun et al. 2015]. Two very recent works [Campen et al. 2021; Gillespie et al. 2021] introduce robust algorithms based on Ptolemy flips to compute conformal maps satisfying a prescribed metric.

All these methods require changing the mesh connectivity of a triangle mesh, and could thus benefit from our framework to simplify their implementation and parallelize the mesh editing operations.

**Mesh Arrangements/Boolean Operations.** Boolean operations are basic algorithms often used in geometry processing applications. Recently, [Zhou et al. 2016] proposed a robust way to compute them by constructing a space arrangement, and then filtering the result using the generalized winding number [Jacobson et al. 2013]. A similar approach, using an approximated meshing algorithm, has been extended in [Hu et al. 2019b], using a tetrahedral mesher to create the initial arrangement. The reimplementation of TetWild introduced in this paper (Section 4) can be extended for a similar purpose.

3 METHOD

Our declarative specification is designed to remove the burden of low-level management of the mesh connectivity and attributes, allowing an algorithm designer to focus only on high-level requirements. The design consists of five components (Figure 2).

3.1 Mesh editing components

**Operation Rollback.** It is common to perform mesh editing to improve a given energy functional, such as mesh quality or element size. However, due to the discrete and combinatorial nature of the operations, it is not possible to use standard smooth optimization techniques to reduce the energy (e.g., Newton’s method or line-search to ensure that the energy decreases). Instead, in such settings, the energy can only be evaluated before and after every operation to measure the operation’s effect. This paradigm is commonly implemented using an ad-hoc energy evaluation that “simulates” the operation only for the purpose of measuring the energy change. This simulation is complex (especially in 3D), and error-prone, as not only the connectivity changes, but the energy likely depends on properties attached to mesh elements, which needs to be updated accordingly.

We propose instead to make this process opaque to the user, providing to the user-code an explicit copy of the mesh (and up to date attributes) before and after the operation is performed to allow an easy and reliable energy evaluation. The correctness and efficiency of this process is handled by the runtime. This reduces the complexity of mesh editing considerably in our experience, as it makes them more similar to traditional finite difference approaches where the energy is evaluated on different points on the domain to approximate its derivative.

**Explicit Invariants.** It is common to have a set of desiderata on the mesh that needs to be satisfied, such as avoiding triangle insertions or self-intersections. Given the complexity of a mesh editing algorithm it is difficult to ensure that they are satisfied, as these conditions need to be checked after every operation is applied (and they often depend on attributes too, such as vertex positions).

We propose to make these invariants explicit, and delegate to the library the task of ensuring that they are checked after every mesh modifications, and after the input is loaded. In this way, not only the code is simpler, but it is much easier to ensure correctness, as the checks are handled transparently by the library.

**Explicit Attribute Update.** Mesh attributes are usually handled by low-level meshing libraries, allowing to attach them to the desired mesh element (vertex, edge, face, triangle, or tetrahedra). However, the handling of attributes after a local operation is performed is usually a responsibility of the user code, as it is dependent on the application.

We propose to make this process more explicit, requiring the user to provide the rules on how to update attributes after operation in a high-level specifications, and delegating the actual update to the library. This makes the specification more direct and less error-prone, and allows users to write algorithms without having to know the low-level details on how the local mesh operations work.

**Parallel Scheduling.** The type and scheduling of local operations is crucial in mesh editing algorithms. It usually involves maintaining a priority queue of operations, which is updated after every local operation.

We provide a direct way of controlling the operations performed and how the queue is updated. In the library, we can then distribute the work automatically on multiple threads, hiding from the
user code the complexity of performing mesh editing operations in parallel and ensuring that race conditions are avoided.

Abstract Mesh Navigation. Both invariant and attribute updates require navigating a mesh. Instead of relying on data-structure specific navigation, we favor the use of the cell tuple abstraction [Brisson 1989]. This allows the specification to be independent of the mesh data structure used in the library. The Tuple stores four indices (three for surface meshes), vertex, edge, face, and tetrahedron and provides a single function per index, called switch, to change one index while keeping the other indices fixed. For instance switch_vertex changes the vertex index while keeping edge, face, and tetrahedron fixed which has the effect of selecting the opposite vertex on an edge.

3.2 Declarative Specification

Our API provides two abstractions: a TetMesh (and TriMesh class for 2D) (Algorithm 1), and a Scheduler (Algorithm 2).

Mesh Classes. Both the TetMesh and TriMesh classes provide the basic local operations (e.g., edge split or collapse) and, for each operation, their corresponding before and after methods. The mesh class is responsible of implementing the operations changing the topology, and the application code must only override the before and after methods to update attributes. The before method has a view of the mesh before the operation, and can thus navigate it to cache local attributes, while the after method has a view after the operation is performed, and it is responsible for updating attributes. In the simple case of regular subdivision of a triangle mesh, the split_before caches the coordinates of the two edge endpoints, and the split_after computes the position of the newly inserted vertex by averaging them.

In addition, the mesh class provides a method, which can be overridden by the user code, that automatically verifies user-provided invariants (e.g., maintain positive elements’ volume). All user-provided methods return a Boolean status to notify the mesh classes if the operation fails; in case it does, our API rolls back the operation and restores the topology to the previous valid state. As the connectivity and attributes management is handled by the class, this ensures that, in case of failure of the operation, the mesh will go back to a valid state.

Our API provides the standard local operations: edge collapsing, edge/face swapping, edge splitting, and smoothing. We also provide an additional, non standard, operation: triangle insertion. This operation is an enhanced version of splitting where multiple edges, faces, and tetrahedra are subdivided to represent an input triangle provided as input. This operation is useful to compute mesh arrangements, and it is also used in meshing algorithms [Hu et al. 2019b].

Since the TetMesh class only handles topology, the operation requires the list of edges and tetrahedron the input triangle intersects. Internally it subdivides all of them, and generates a valid tetrahedral mesh using the connectivity table in [Hu et al. 2019b]. The before operation provides the user the list of faces that will be changed by the operation, allowing the user code to explore the mesh and

Algorithm 1 API of our TetMesh class.

```cpp
class TetMesh
{
public:
    bool split_edge(const Tuple& t, std::vector<Tuple>& new_tets);
    bool collapse_edge(const Tuple& t, std::vector<Tuple>& new_tets);
    bool swap_edge(const Tuple& t, std::vector<Tuple>& new_tets);
    bool swap_face(const Tuple& t, std::vector<Tuple>& new_tets);
    bool smooth_vertex(const Tuple& t);
    bool insert_triangle(const Tuple& t);

protected:
    bool invariants(const std::vector<Tuple>& tets);
    bool split_before(const Tuple& t);
    bool split_after(const Tuple& t);
    bool collapse_before(const Tuple& t);
    bool collapse_after(const Tuple& t);
    bool swap_edge_before(const Tuple& t);
    bool swap_edge_after(const Tuple& t);
    bool swap_face_before(const Tuple& t);
    bool swap_face_after(const Tuple& t);
    bool smooth_before(const Tuple& t);
    bool smooth_after(const Tuple& t);
    bool insert_triangle_before(const std::vector<Tuple>& faces);
    bool insert_triangle_after(const std::vector<Tuple>& faces);
};
```
We implement a runtime for our specification in C++, using Intel oneTBB for parallelization.

Algorithm 2 API of our Scheduler.

```cpp
template <class Mesh>
struct Scheduler {
    function<double, Op op, const Tuple&>
        priority = ...;

    function<vector<pair<Op, Tuple>>&>
        renew_neighbor_tuples = ...;

    function<vector<size_t>>
        lock_vertices = ...;

    function<bool(Mesh&)> stopping_criterion = ...;

    function<bool>
        (Mesh& m, tuple<Op, Tuple>& t)
        should_process = ...;

    size_t num_threads = ...;
    size_t max_retry_limit = ...;
    size_t stopping_criterionChecking_frequency = ...;

    bool operator() (Mesh& m, const vector<pair<Op, Tuple>>& ops);
};
```

3.3 Implementation.
We implement a runtime for our specification in C++, using Intel oneTBB for parallelization.

Scheduler. The second part of our API is the Scheduler that is responsible to control the order of the individual operations and then execute a list of operations. The main purpose of the scheduler is to abstract the operation order and hide parallelization details from the user. Our scheduler provides customizable callbacks, including,

- **Priority** to order the local mesh edit operations.
- **Renew neighbor tuples** that is invoked after a successful operation, to add newly created tuples and operations into the queue.
- **Lock vertices** that provides information on the affected region for the operations, and avoiding conflicts.
- **Stopping criterion** that is checked periodically to terminate the program if certain criterion is met. For example, number of vertices, or quality criterion.

Fig. 3. Example of the locking region for two edges. In the example the operation requires locking a two-ring neighborhood (e.g., for the edge collapse operation). If the two edges are sufficiently far (right) both operations can be safely executed in parallel. When the two edges are close (left) the operations might fail acquiring the mutexes in the shared area.

Data Structure. We opt for an indexed data structure, where we explicitly represent the vertices and the simplex of higher dimension (triangle for 2D, tetrahedra for 3D). Each vertex explicitly stores a list of incident simplices, and each simplex stores a sorted list of its vertices. While not the most efficient option for navigation, this data structure makes the implementation of local operations much simpler.

Parallelization. To avoid conflicts between local operations working on the same part of the mesh, we introduce a synchronization mechanism using locks.

Each mesh vertex is associated with a mutex. Whenever a thread wants to access (read/write) any attribute stored in a vertex, edge, triangle, or tetrahedron it must first acquire a lock on all the vertices of the tetrahedron containing the element(s) storing the attribute (Figure 3). For example, if a thread wants to read a value on an edge of a 3D mesh, it first needs to acquire a lock on all vertices of all the tetrahedra containing that edge. This mechanism is used also for mesh navigation, and for updating the mesh connectivity.

At a first look, this mechanism might seem cumbersome and expensive. However, we rely on asynchronous, tentative lock acquisition operations. We try to acquire the lock, and give up and release all previously acquired locks if the lock is already taken by another thread. These operations are efficient on modern hardware and dramatically improve the performance, while avoiding deadlocks: the locking region is dependent on the local operation, and for all the operation we implement (edge split, collapse, flip, and vertex smoothing), the two-ring neighborhood is sufficient to prevent a deadlock. A downside is that an operation might be skipped due to impossibility of acquiring a mutex. These operations are retried for several times (by default 10 times) and run serially if the still do not succeed. Before performing any local operation, we try to acquire the lock on vertices in the 1-ring or 2-ring of the vertex involved in the operation. For example, a vertex smoothing operation requires acquiring the 1-ring vertex neighborhood of the smoothed vertex, while an edge-collapse operation on an edge (v1, v2) requires acquiring the lock on the 2-ring vertex neighborhood of both v1 and v2 (Figure 3).

Finally, since we partition the input mesh using Morton Encoding [Karras 2012], the amount of conflicts (and skipped operations) is low.
3.4 Example: Shortest Edge Collapse

We show how the library is used in a classical example, shortest edge collapse. In this case, we add a 3D position to every vertex as a vertex attribute (by default, there are no attributes attached to mesh elements). For every attribute and for every operations we plan to use in the scheduler, we need to provide a function that updates such attribute (Algorithm 3). In the collapse_before function, we cache the two vertex coordinates associated with the collapsed edge represented by Tuple t. In the collapse_after function, we generate a new vertex in the middle of the two endpoints of the collapsed edge.

Algorithm 3 Overridden methods in TriMesh sub-class to implement shortest edge collapse.

```cpp
//Save two vertices attached to edge t
bool collapse_before(const Tuple& t) {
    cache.v1p = verts[t.v1p()];
    cache.v2p = verts[t.switch_vertex().v2p()];
    return true;
}

//Generate a new point
bool collapse_after(const Tuple& t) {
    verts[t.v1p()] = (cache.v1p + cache.v2p) / 2.0;
    return true;
}
```

Equipped with the 3D position attribute, which at this point will be automatically kept up to date by the library, we can now schedule the collapse operation (Algorithm 4). For shortest edge collapse, we want to attempt to collapse all edges, prioritizing the shorter ones, until we reach a fixed number of collapses n_collapse: in the code we registering the operation type (ops), specify how to update the queue after an operation (renew) by adding all the neighbouring edges, and specifying the edge length as a priority (priority). Note that the outdated elements in the queue that are affected by a local operation are automatically invalidated using a tagging mechanism on the tuples which is opaque to the user.

4 APPLICATIONS

To showcase the generality and effectiveness of our approach, we implement five popular mesh editing algorithms in our framework, and compare them with reference implementations. Overall, the performance of our method are competitive for surface applications, but the overhead due to the approach generality is higher in 3D, leading to higher running time.

Shortest Edge Collapsing. The simplest algorithm for simplifying a triangle edge is shortest edge collapse [Hoppe 1996], which performs a series of collapse operations prioritizing the shorter edges. The algorithm requires only one local operation, edge collapse. A common criteria for termination is reaching a desired number of mesh elements. We compare our implementation with the “decimate” implementation in libigl [Jacobson et al. 2016]. The serial

Algorithm 4 Scheduler setup for the schedule shortest edge collapse.

```cpp
//Collect edges attached to tris
vector<Tuple> new_edges_after(const vector<Tuple>& tris) {
    vector<Tuple> new_edges;
    for (auto t : tris) {
        for (auto j = 0; j < 3; j++) {
            new_edges.push_back(tuple_from_edge(t.fid(), j));
        }
    }
    return new_edges;
}

bool collapse_shortest(int n_collapses) {
    //Register operations
    auto ops = vector<pair<Op, Tuple>>();
    for (auto& l : get_edges())
        ops.emplace_back("edge_collapse", l);
    //After a successful operation,
    //we append all new edges
    auto renew = []([auto& m, auto op, auto& tris] {
        auto edges = m.new_edges_after(tris);
        auto optup = vector<pair<Op, Tuple>>();
        for (auto& e : edges)
            optup.emplace_back("edge_collapse", e);
        return optup;
    });
    //priority in which we collapse
    auto priority = []([auto& m, auto op, const Tuple& e] {
        const auto v1 = m.verts[e.v1p()];
        const auto v2 = m.verts[e.switch_vertex().v2p()];
        auto len2 = (v1 - v2).squaredNorm();
        return -len2;
    });
    //Set the functions to the scheduler
    Scheduler executor;
    executor.renew_neighbor_tuples = renew;
    executor.priority = priority;
    executor.stopping_criterion_checking_frequency = n_collapses;
    //We stop only when we perform n_collapses
    executor.stopping_criterion = []([auto& m] { return true; });
    //Run the executor
    executor(*this, ops);
}
libigl implementation is comparable when running the algorithms serially, and our parallel implementation is up to 9 times faster when using 32 threads (Figure 4).

**QSlim.** We use our framework to implement QSlim [Garland and Heckbert 1997]. QSlim collapse edges based on the planarity of the two adjacent faces measured with an error quadric. The algorithm continues to collapse until it reaches a target number of edges. We compare our implementation with the QSlim implementation in libigl [Jacobson et al. 2016]. The serial libigl implementation is 8 times faster than our implementation, due to their direct manipulations of elements in the queue with each collapse. But our parallel implementation is twice as fast when using 16 threads (Figure 5).

**Isotropic Remeshing.** We implemented the widely used algorithm for isotropic remeshing proposed in [Botsch and Kobbelt 2004]. This algorithm alternates edge collapse, edge flips, edge splits, and tangential smoothing to obtain a mesh that is isotropic (i.e., all elements have the same size) and where all triangles are close to equilateral. The process is guided by a user-provided target edge length \( L \), and terminates when no local operation leads to either an improvement in the desired edge lengths or an improvement in vertex valence [Botsch and Kobbelt 2004].

In Figure 6, we compare our implementation of [Botsch and Kobbelt 2004] with the implementation in OpenFlipper [Möbius and Kobbelt 2010]. The OpenFlipper implementation is 2.5 times faster when running on a single thread, and our implementation becomes faster after 4 threads are used (Figure 6).

**Harmonic Triangulations.** The harmonic triangulations algorithm has been introduced as an alternative to sliver exudation in the Delaunay tetrahedralization pipeline to efficiently reduce sliver tetrahedra. The original paper [Alexa 2019] proposes to use both flip and smoothing operations.

The code provided by the authors implements a reduced version of the algorithm proposed in the paper, restricting the optimization to 3-2 edge swap operations. We thus implemented both a reduced version for a fair comparison (Figure 7) and a complete version. Our more generic framework is twice as slower than the hand-optimized code written by the authors when running serially, and it is 2 times faster when running on 32 threads (Figure 7).

**Tetrahedral Meshing.** The TetWild algorithm is a tetrahedral meshing algorithm with minimal input requirements: given an input triangle soup, it can generate a tetrahedral mesh which approximates its volume. We take inspiration from the original algorithm introduced in [Hu et al. 2019b, 2018] with a few modifications: (1) we use the insertion operation [Hu et al. 2019b] (using rational coordinates) as a replacement for their BSP partitioning, as this simplifies the implementation, (2) we use the envelope proposed in [Wang et al.
2020] instead of sampling, and (3) we use 2-3 face swapping, 3-2 and 4-4 edge swapping operations, to simplify the implementation. We show results on two models in Figure 8: the results are very similar to the original implementation, and our version is 2 times faster when using 8 threads. We experimentally observe that our framework scales well up to 8 threads, after that the algorithm becomes slower. This is because, as we increase the number of threads and partitions, the frequent conflict in tetrahedral mesh edge operations affects the parallel performance. We believe that this observation might be useful for the future design of high performance concurrent mesh generation algorithms. We also measure the qualities of resulting tetrahedral meshes in Figure 9. Note that due to various different implementation design, our performance and quality may be better or worse compared with TetWild[Hu et al. 2019b]. Fine tuning our performance and a large scale comparison is beyond the scope of this work.

4.1 Parallelization

Enabling the parallelization mechanism introduces a minor slowdown as visible in the difference between the pure serial and one thread timings on our applications, due to the additional cost of allocating mutexes and to acquire them. Additionally, due to the nature of parallelization, our concurrent implementation is not deterministic. The differences between different runs are however minor: we run uniform remeshing on the model in Figure 6 five times and obtained an average vertex valence of 5.999 with a standard deviation of 9.885 × 10⁻². The average Hausdorff distance is 0.5% of the size of the bounding box diagonal compared to the serial result, with a standard deviation of 0.2%. The algorithm scales well in all 5 applications (Figures 4, 5, 6, 7, 8), obtaining a scaling speedup (see the timing breakdown and the additional overhead in Table 1). We would like to remark that thanks to our specification and our runtime, the serial and parallel implementation of the five algorithms above is almost identical.

An inevitable drawback of parallelization is that the algorithms cannot efficiently preserve ordering. For instance, in shortest edge collapse, every thread will try to collapse edges in its own partition

Table 1. Timings of the serial version compared with the single threaded version, which has additional overhead due to the unnecessary locking/unlocking.
To validate our framework we run our reimplementation of uniform and Jacobson 2016. We run all experiments serially on an individual node of an HPC cluster an Intel Xeon Platinum 8268 24C 205W 2.9GHz Processors limiting the runtime to 15 hours.

For uniform remeshing, Figure 13 shows the time, average edge length normalized by the target, and average valence of isotropic remeshing on the ten thousand models. Most of our models finish within 10 seconds with only a few requiring more than a minute. For almost all meshes, the algorithm succeeds at reaching the target edge length and valence of 6.

For TetWild we limit the number of iterations to 25 (Figure 14). We note that within the 15 hours limit only 2.5% models did not finish, and after 25 iterations 3% of the models still have some rational coordinates. Among the successful models, most finish within 20 minutes and succeed in achieving high-quality meshes (only 8 models have an average AMIPS energy larger than 10).

4.2 Algorithm Modifications

A major motivation to invent and develop this declarative language is enabling easy customization of meshing algorithms. As an example, we add an additional termination criteria to the shortest edge collapse and uniform surface refinement. Integrating the envelope check is straightforward with our approach, as it only requires adding the envelope check to the invariants. We use the open-source library proposed in [Wang et al. 2020], which allows to directly specify the maximal allowed surface deviation. The envelope adds a noticeable computational cost, which is ameliorated by our parallel implementation (figures 11 and 12).

4.3 Large-scale dataset validation

To validate our framework we run our reimplementation of uniform remeshing and tetrahedral meshing on the Thingi10k dataset [Zhou and Jacobson 2016]. We run all experiments serially on an individual
5 CONCLUDING REMARKS

This paper introduces a new declarative specification for mesh algorithms based upon five guiding principles (Section 3.1) to allow an easier implementation, while at the same time obtaining competitive performance and exploiting parallel hardware. We note that the principles are based on our experience in mesh optimization and not necessarily the only or optimal choices. A more formal justification would be interesting to explore in the future.

Using this specification, we implement five popular mesh editing algorithms covering mesh generation and optimization on surfaces and volumes, which can be easily adapted for other use cases: we demonstrated that integrating an envelope check requires only a few lines of code.

The library we implemented supports shared memory parallelism, which leads to a good scaling on the machines we tested it on. We believe an exciting venue for future work would be the implementation of a library for our specification targeting MPI to distribute the computation over an HPC cluster. Having access to such a library would allow our five mesh editing applications to run on a distributed environment with minimal or no changes.
